

A 2-ADIC OBSTRUCTION TO MODULAR LYAPUNOV FUNCTIONS FOR THE $3n + 1$ PROBLEM

TULLIO MARCHETTO

ABSTRACT. Let T be the accelerated Collatz map: $T(n) = n/2$ for even n , $T(n) = (3n+1)/2$ for odd n . We prove, by an elementary and self-contained argument, that for every $j \geq 1$ no function of the form $V(n) = \log_2 n + w(n \bmod 2^j)$, with $w : \mathbb{Z}/2^j\mathbb{Z} \rightarrow \mathbb{R}$ arbitrary, decreases strictly at every positive odd integer. The obstruction comes from the fixed point $-1 \in \mathbb{Z}_2$: its projection at every finite level carries positive representatives with logarithmic gain $\log_2 3 - 1 > 0$, while the modular correction cancels. The conclusion persists with finite exceptions, non-strict inequality, and blocks of k iterations. The hypothesis is imposed only on $\mathbb{Z}_+$, where no cycle other than $\{1, 2\}$ is known. **Question:** does this positive-integer formulation appear explicitly in the literature?

1. STATEMENT AND PROOF

Let $T : \mathbb{Z} \rightarrow \mathbb{Z}$ be the accelerated Collatz map, $T(n) = n/2$ for n even and $T(n) = (3n + 1)/2$ for n odd. The Collatz conjecture asserts that every $n \geq 1$ reaches the cycle $\{1, 2\}$ under iteration of T [2, 3]. Since the length- k parity vector is determined by the residue modulo 2^k [6], finite periodic corrections to the logarithmic scale form a natural class of candidate descent certificates. The result below shows that this class is empty.

Definition 1 (Modular Lyapunov function). Fix $j \geq 1$. A *modular Lyapunov function of level j* is a function

$$V(n) = \log_2 n + w(n \bmod 2^j), \quad w : \mathbb{Z}/2^j\mathbb{Z} \rightarrow \mathbb{R} \text{ arbitrary,}$$

such that $V(T(n)) < V(n)$ for every odd integer $n > 0$.

Since w has finite domain, it is bounded and acts on the integers as a periodic potential of period 2^j . If such a V existed, no positive orbit could diverge.

Theorem 2 (Modular obstruction). *For every $j \geq 1$ and every $w : \mathbb{Z}/2^j\mathbb{Z} \rightarrow \mathbb{R}$, the function $V(n) = \log_2 n + w(n \bmod 2^j)$ is not strictly decreasing along the odd steps of T in $\mathbb{Z}_+$. Specifically, the projection of the 2-adic fixed point $-1 \in \mathbb{Z}_2$ onto $\mathbb{Z}/2^j\mathbb{Z}$ induces, on the class $-1 \bmod 2^j$, a loop of logarithmic gain $\log_2 3 - 1 > 0$ that no potential w compensates.*

Proof. Suppose, for contradiction, that there is $w : \mathbb{Z}/2^j\mathbb{Z} \rightarrow \mathbb{R}$ such that, for every odd $n > 0$,

$$(1) \quad w(T(n) \bmod 2^j) - w(n \bmod 2^j) < -\log_2 \frac{T(n)}{n}.$$

Consider the family $n_m = 2^{j+1}m - 1$, $m \geq 1$. Since $j \geq 1$ we have $n_m \geq 3$; every n_m is therefore a strictly positive odd integer, contained in the domain where (1) is assumed. The accelerated step evaluates exactly:

$$T(n_m) = \frac{3(2^{j+1}m - 1) + 1}{2} = 3 \cdot 2^j m - 1.$$

Reducing modulo 2^j ,

$$n_m = 2^j(2m) - 1 \equiv -1, \quad T(n_m) = 2^j(3m) - 1 \equiv -1 \pmod{2^j}.$$

Substituting n_m into (1), the potential terms cancel identically, leaving, for every $m \geq 1$,

$$0 < -\log_2 \frac{3 \cdot 2^j m - 1}{2 \cdot 2^j m - 1}.$$

This requires the argument of the logarithm to be strictly less than 1; since numerator and denominator are positive, that means $3 \cdot 2^j m - 1 < 2 \cdot 2^j m - 1$, i.e. $3 < 2$ — a contradiction. $\square$

Remark 3 (The mechanism). In $\mathbb{Z}_2$ the integer -1 is an odd fixed point of the accelerated map: $T(-1) = (3 \cdot (-1) + 1)/2 = -1$. Any function of the residues modulo 2^j is blind to the difference between the positive integers $n_m \equiv -1 \pmod{2^{j+1}}$, which we want to control, and the point $-1 \in \mathbb{Z}_2$ they approach 2-adically, on which the dynamics genuinely gains $\log_2 \frac{3}{2} = \log_2 3 - 1 > 0$ per step. The family n_m transports this stationary gain into $\mathbb{Z}_+$, where the potential cancels and only the gain remains. The obstruction is therefore *structural*: it does not depend on the combinatorics of w , only on the existence of the 2-adic fixed point.

2. ROBUSTNESS

Corollary 4 (Robustness). *The obstruction of Theorem 2 persists under each of the following relaxations of Definition 1.*

- (1) Finite exceptions. *If (1) is only required outside a finite set $E \subset \mathbb{Z}_+$, no such V exists.*
- (2) Non-strict decrease. *If the requirement is weakened to $V(T(n)) \leq V(n)$, no such V exists.*
- (3) Blocks of k iterations. *If the requirement is $V(T^k(n)) < V(n)$ for a fixed $k \geq 1$, no such V exists.*
- (4) Restricted domains. *If the decrease is required only on a subset $D \subseteq \mathbb{Z}_+$ of the odd integers, then either D omits infinitely many terms of some family $n_m = 2^{j+1}m - 1$ — in which case V cannot certify global convergence — or D contains infinitely many of them, and no such V exists.*

Proof. (1) The family $\{n_m\}_{m \geq 1}$ is infinite; for any finite E there is m with $n_m \notin E$, and the proof of Theorem 2 applies verbatim to that m .

(2) With $\leq$ in place of $<$, the final inequality becomes $3 \leq 2$, still false.

(3) Parametrize the deeper family $n_m = 2^{j+k}m - 1$, $m \geq 1$. By induction, $T^i(n_m) = 3^i 2^{j+k-i}m - 1$ for $0 \leq i \leq k$, each of the first k steps being odd: if $i < k$, then $j+k-i \geq j+1 \geq 2$, so $3^i 2^{j+k-i}m$ is even, $T^i(n_m)$ is odd, and

$$T^{i+1}(n_m) = \frac{3(3^i 2^{j+k-i}m - 1) + 1}{2} = 3^{i+1} 2^{j+k-i-1}m - 1.$$

Hence $T^k(n_m) = 3^k 2^j m - 1 \equiv -1 \equiv n_m \pmod{2^j}$: the potentials cancel in the block inequality, leaving $0 < -\log_2 \frac{3^k 2^j m - 1}{2^k 2^j m - 1}$, which forces $3^k < 2^k$, false for every $k \geq 1$.

(4) If D contains infinitely many n_m , run the proof of Theorem 2 on those; if it omits all but finitely many, the orbits through the omitted integers are left entirely unconstrained by V . $\square$

3. RELATION TO THE LITERATURE, AND THE QUESTION

That *some* obstruction to modular Lyapunov functions must exist over all of $\mathbb{Z}$ is unsurprising: the negative integers contain genuine cycles (-1 ; $-5 \rightarrow -7 \rightarrow -10$; and the cycle of -17), and a strictly decreasing V on $\mathbb{Z} \setminus \{0\}$ would forbid them. Moreover, the underlying phenomenon is folklore: it has been understood since the stopping-time analyses of Terras [6] and Everett [1] that the residue class $-1 \pmod{2^k}$ rises for k consecutive accelerated steps (e.g. $n = 2^k - 1$), so no descent argument reading only a fixed finite dyadic residue can be uniform.

The content of Theorem 2 is the precise packaging of this phenomenon as a *nonexistence* statement for the class of Definition 1: the hypothesis is imposed *only* on $\mathbb{Z}_+$, where no cycle other than $\{1, 2\}$ is known, and the failure is nevertheless unconditional — caused by the projection of the single 2-adic point -1 , not by any cycle in the domain of the hypothesis. We make no claim of priority; we regard the theorem as a formalization of a known heuristic, in the spirit of the average-descent results of [6, 5]. The closest reputable relative is a no-go of a different kind: Kohl [4] shows the permutation conjugating an almost-contracting residue-class-wise affine map cannot itself be such a map — a statement about a *conjugacy*, not an additive $\log_2 n + w(n \bmod 2^j)$ potential.

The question motivating this note: is this formulation — nonexistence of a strictly decreasing $V(n) = \log_2 n + w(n \bmod 2^j)$ on the positive odd integers, with the robustness of Corollary 4 — stated explicitly anywhere in the $3x+1$ literature? A systematic search (Lagarias’s bibliographies, arXiv, citation chasing) did not locate it; we ask for a pointer to any source it missed. References or corrections are most welcome.

The full manuscript (with additional Wasserstein-contraction results and a reproducible exact-arithmetic computational laboratory) is available at <https://github.com/tuliomarchetto/collatz>.
